# A Suggested Computation for Maximal Multi-Commodity Network Flows 

L. R. Ford Jr., D. R. Fulkerson<br>The RAND Corporation, Santa Monica, California

#### Abstract

Asimplex computation for an arc-chain formulation of the maximal multi-commodity network flow problem is proposed. Since the number of variables in this formulation is too large to be dealt with explicitly, the computation treats non-basic variables implicitly by replacing the usual method of determining a vector to enter the basis with several applications of a combinatorial algorithm for finding a shortest chain joining a pair of points in a network.

History: Received October 1957.

## 1. Introduction

A problem of some importance in applications of linear programming is the determination of maximal multi-commodity flows in networks. For example, some of the linear programming problems which have been proposed recently by Kalaba and Juncosa in their studies of communication networks (1956) can be cast in this form. Straightforward application of the simplex method to such problems is usually not feasible, since even small networks may generate linear programs which are too large for present machine capacity. What is needed are specialized computing schemes that take advantage of the structure of such problems. For the single commodity case, various easy computations are known (Dantzig and Fulkerson 1955; Ford and Fulkerson 1956, 1957), but the multi-commodity problem has remained relatively unexplored.

Consideration of simple examples makes it appear that the multi-commodity flow problem is considerably more complex than the single commodity one. Certainly the nice combinatorial features of the single commodity case are lost in the generalizationsimplex bases (for any formulation of the problem known to us) are not triangular, hence addition and subtraction do not suffice to solve such problems by the simplex method, the max flow min cut theorem, true for single commodity networks, is false (Ford and Fulkerson 1956), and no simple-minded modification of the labeling process (Ford and Fulkerson 1957) seems to work.

The purpose of this note is to suggest a computation which makes some use of the structure of one formulation of the multi-commodity problem within the framework of a simplex computation. For this
particular formulation, the matrix of the linear program is the incidence matrix of arcs vs. all chains joining sources and sinks for the various commodities, and thus the number of variables is too large to be dealt with explicitly. The suggested computation treats non-basic variables implicitly by replacing the "pricing" operation of the simplex method (i.e. the determination of a vector to enter the basis) with several applications of a combinatorial algorithm for finding a shortest chain joining a pair of points in a network.

## 2. Arc-Chain Formulation

Let $A_{1}, \ldots, A_{m}$ be a list of the arcs of the network, $C_{1}, \ldots, C_{n}$ a list of all chains that join, for the various commodities, all the sources for a commodity with all sinks for the same commodity, and let $A=\left(a_{r s}\right)$ be the $m \times n$ incidence matrix of arcs vs. commodity chains:

$$
a_{r s}= \begin{cases}1 & \text { if } C_{s} \text { contains } A_{r}  \tag{1}\\ 0 & \text { otherwise }\end{cases}
$$

Thus, for example, if the network is that of Figure 1, with sources $P_{1}, P_{2}$, sink $P_{3}$ for one commodity, and source $P_{4}$, sink $P_{1}$ for a second commodity, the matrix A is as shown in Figure 2.

If we let $x_{s}, s=1, \ldots, n$, denote the amount of commodity flow along $C_{s}$, and $b_{r}$ the flow capacity of $A_{r}$, then the multi-commodity maximal flow problem is represented by the linear program:

$$
\begin{equation*}
\text { maximize } \sum_{s=1}^{n} x_{s} \tag{2}
\end{equation*}
$$

subject to the constraints

$$
\begin{equation*}
\sum_{s=1}^{n} a_{r s} x_{s}+x_{n+r}=b_{r}, \quad x_{1}, \ldots, x_{n+r} \geqq 0 . \tag{3}
\end{equation*}
$$

Figure 1

The assumption in (2) that commodities are valued equally is not essential to the method we propose, as will be clear from our discussion in the following section. Another thing we wish to point out is that it is immaterial whether the problem involves directed or undirected arcs. Thus, for example, if there are "oneway streets," or if, in a communication network, say, it is desired to place an upper bound on the number of messages that can be transmitted from $P_{i}$ to $P_{j}$, and an upper bound on the messages that can be sent from $P_{j}$ to $P_{i}$, one considers two arcs, one from $P_{i}$ to $P_{j}$, the other from $P_{j}$ to $P_{i}$, and directed chains from sources to sinks.

Since the number of chains is usually very large in practical applications, the arc-chain formulation of the problem might seem to be impossible to deal with computationally. Indeed, the enumeration of all chains from commodity sources to sinks in a network of moderate size would be a lengthy task, to say the least. Fortunately, there is no need to write down the entire matrix $A$, since the selection of a variable entering the basic set at any stage of the simplex computation (or the recognition that a basis is optimal) can be accomplished without explicit knowledge of the non-basic column vectors of $A$. All we need is the basis $B=\left(b_{r j}\right)$ (or its inverse), a square submatrix whose order is the number $m$ of arcs in the network, to compute the simplex multipliers $\alpha_{r}(r=1, \ldots, m)$ satisfying, for $j=s_{1}, \ldots, s_{m}$,

$$
\sum_{r=1}^{m} \alpha_{r} b_{r j}= \begin{cases}1 & \text { if } j \leqq n  \tag{4}\\ 0 & \text { if } j>n\end{cases}
$$

We can then find a vector to bring into the basis (or prove that the current basis is optimal) by the
method of the next section. Once such a vector has been found, determination of the vector leaving the basis is accomplished in the usual way.

## 3. A Shortest Chain Algorithm

Suppose we have computed the $\alpha_{r}$ in (4) corresponding to a particular basis $B$. If some $\alpha_{r}$, is negative, then the variable $x_{n+r}$ may be introduced into the basic set with possibly an increase in the form (2), that is, the unit vector having 1 in the $r$-th position, zeros elsewhere, can be brought into the basis. (It may be that this vector also represents a one-arc chain for some commodity; in this case, a bigger increase in (2) might result, of course, by taking the latter interpretation.)

Assume, therefore, that a stage has been reached in the computation where all $\alpha_{r}$ are non-negative. In this case, the algorithm described below, which makes no use of the full incidence matrix $A$, can be used either to locate a column vector of $A$ (i.e. a commodity chain in the network), that may be brought into the basis, or to prove that the current basis is optimal.

Let us interpret the $\alpha_{r}$ as lengths of the arcs. We wish to find a chain $C_{s}$, if one exists, whose length

$$
\sum_{r=1}^{m} \alpha_{r} a_{r s}
$$

is less than one, the coefficient of $x_{s}$ in (2). Thus, it suffices to locate, for each commodity, a shortest chain from the commodity sources to its sinks. If each of the chains thus selected has length at least one, the basis is optimal. Otherwise, a column vector of $A$ corresponding to one of these chains may be introduced into the basis.

The problem of locating a shortest chain from one set of nodes to another set of nodes in a network can be reduced to a standard transshipment problem (Orden 1956), and may consequently be solved in various simple ways; see Ford (1956) and Orden (1956), for example. The algorithm we describe is that of Ford (1956). (In Ford (1956), the problem is considered to be that of finding a shortest chain from one node to another; to reduce our problem to this one, simply join each node of the first set to a new node by an arc of length zero, and similarly for the other set. We shall

Figure 2

| $\quad$$A_{1}$ <br> $A_{2}$ <br> $A_{3}$ <br> $A_{4}$ <br> $A_{5}$ <br> $A_{6}$ |
| :--- |$C_{2}$

give a description which does not involve this device explicitly, however.)

Let the set of sources for one commodity be $S$, the sinks for the commodity $T$, and suppose the nodes of the network are $P_{1}, \ldots, P_{N}$. Let $l_{i j}$ denote the length of the arc joining $P_{i}$ and $P_{j}$, i.e. if the arc $A_{r}$, joining $P_{i}$ and $P_{j}$ corresponds to the simplex multiplier $\alpha_{r}$, set $l_{i j}=\alpha_{r}$. (If arcs are directed, then we let $l_{i j}$ denote the multiplier corresponding to the arc from $P_{i}$ to $P_{j}$, hence in this case we may have $l_{i j} \neq l_{j i}$, whereas in the undirected case, $l_{i j}=l_{j i}$.) Initially assign to each node $P_{i}$ a number $\pi_{i}$ as follows:

$$
\pi_{i}= \begin{cases}0 & \text { for } P_{i} \in S \\ \infty & \text { otherwise }\end{cases}
$$

Now scan the network for an $\operatorname{arc} P_{i} P_{j}$ such that

$$
\pi_{i}+l_{i j}<\pi_{j}
$$

Replace $\pi_{j}$ by $\pi_{i}+l_{i j}$ if such an arc is found. Continue this process. Eventually no such arcs can be found; then the number $\pi_{i}$ represents the length of a shortest chain from $S$ to $P_{i}$, for all $i$. In particular, the smallest $\pi_{i}$, for $P_{i} \in T$, is the length of a shortest chain from $S$ to $T$. Let $\pi_{k}$ be the smallest such. To find a chain from $S$ to $T$ of length $\pi_{k}$, look for an arc $P_{j} P_{k}$ such that $\pi_{j}+l_{j k}=\pi_{k}$, then search for an arc $P_{i} P_{j}$ such that $\pi_{i}+l_{i j}=\pi_{j}$, and so on. Eventually a node of $S$ is reached, and the desired chain has been traced out (in reverse).

If in the process of locating shortest chains from commodity sources to sinks, for the various commodities, one is found of length less than one, we recommend that the corresponding column vector of $A$ be introduced into the basis immediately, rather than repeating the shortest chain algorithm a number of times in order to use the usual criterion for selection of a vector to enter the basis.

We point out that the reason for getting rid of negative multipliers $\alpha_{r}$ before using the shortest chain algorithm is that the algorithm may not work if arcs have negative lengths.

To start the simplex computation, one can of course begin with the basic variables $x_{n+1}, \ldots, x_{n+r}$, corresponding to the zero flow.

## 4. Concluding Remarks

Except for hand computation of a few small problems, we have no computational experience with the proposed method. Whether the method is practicable for a problem involving, say, 50 nodes, 100 arcs, and 20 commodity source-sink sets $S_{1}, T_{1}, \ldots, S_{20}, T_{20}$, is a question which can be settled only by experimentation. It would certainly be more practicable in
this case than straight-forward application of the simplex method to a node-arc formulation of the problem, since in the latter formulation there would be roughly 1100 equations in 2100 variables, and hence the basis matrices would be much too large, whereas in the suggested method, the basis matrices would be $100 \times 100$, and at most 20 applications of the shortest chain algorithm would be necessary on each simplex iteration. How many simplex iterations might be required is another matter, though. The incidence matrix $A$ for such a problem could have many thousands of columns. On the other hand, there would probably be many column vectors of $A$ dominated by others, in the sense that, for a given commodity (or for different commodities in the equal value case), if one chain $C$ is a subset of another chain $C^{\prime}$, then $C^{\prime}$ can be ignored. (For instance, the chain $C_{1}$ of Figure 2 dominates $C_{8}$ and $C_{9}$.) The shortest chain method takes care of such dominances automatically.

A more serious consideration is how to handle the case of limited supplies of commodities in such a problem. For example, suppose that in the two commodity maximal flow problem corresponding to the matrix of Figure 2, there is an amount $a_{1}$ of commodity 1 at $P_{1}$, an amount $a_{2}$ of commodity 1 at $P_{2}$, and an amount $a_{4}$ of commodity 2 at $P_{4}$. We can reduce this to a problem of the same type as before by introducing three new directed arcs and nodes as follows: $A_{1}^{\prime}$ from $P_{1}^{\prime}$ to $P_{1}$ with capacity $a_{1}, A_{2}^{\prime}$ from $P_{2}^{\prime}$ to $P_{2}$ with capacity $a_{2}$, and $A_{4}^{\prime}$ from $P_{4}^{\prime}$ to $P_{4}$ with capacity $a_{4}$. We then take $P_{1}^{\prime}, P_{2}^{\prime}$ as sources for commodity 1 , and $P_{4}^{\prime}$ as the source for commodity 2 . However, in the hypothesized large network with 20 commodities, the number of such new arcs would be $\sum_{i=1}^{20} n_{i}$, where $n_{i}$ is the number of nodes in $S_{i}$, and since each new arc increases the size of basis matrices by one, this might take the problem out of range of present computing machines.
